Maximally random jammed (MRJ) sphere packing is a prototypical example of a system naturally poised at the margin between underconstraint and overconstraint. This marginal stability has traditionally been understood in terms of isostaticity, the equality of the numbers of mechanical contacts and degrees of freedom. Quasicontacts, pairs of spheres on the verge of coming in contact, are irrelevant for static stability, but they come into play when considering dynamic stability, as does the distribution of contact forces. We show that the effects of marginal dynamic stability, as manifested in the distributions of quasicontacts and weak contacts, are consequential and nontrivial. We study these ideas first in the context of MRJ packing of $d$-dimensional spheres, where we show that the abundance of quasicontacts grows at a faster rate than that of contacts. We reexamine a calculation of Jin et al. (Phys. Rev. E 82, 051126, 2010), where quasicontacts were originally neglected, and we explore the effect of their inclusion in the calculation. This analysis yields an estimate of the asymptotic behavior of the packing density in high dimensions. We argue that this estimate should be reinterpreted as a lower bound. The latter part of the paper is devoted to Bravais lattice packings that possess the minimum number of contacts to maintain mechanical stability. We show that quasicontacts play an even more important role in these packings. We also show that jammed lattices are a useful setting for studying the Edwards ensemble, which weights each mechanically stable configuration equally and does not account for dynamics. This ansatz fails to predict the power-law distribution of near-zero contact forces, $P(f) \sim f^\theta$.

I. INTRODUCTION

The margin between underconstraint and overconstraint in the stability of disordered systems is associated with many unusual and not completely understood phenomena, such as glass formation in covalently bonded materials [1], peaks in computational complexity in NP-hard problems [2], and critical heterogeneity in mechanical response of elastic networks [3]. Randomly packed frictionless hard spheres at the jamming transition are a prototypical example of a system that is driven from the region of underconstraint just to the edge of overconstraint. Maximally random jammed (MRJ) packings are those that exhibit the least order, as measured by a variety of different order metrics, from the set of all strictly jammed (mechanically stable) packings [4]. Such packings are naturally poised at the critical margin without the need to tune parameters. The idea of marginal constraint in MRJ configurations has long been synonymous with isostaticity, the equality between the number of mechanical contacts between spheres and the number of translational degrees of freedom [5]. Recently, however, it has been argued that in addition to marginal constraint from the point of view of mechanical stability, MRJ configurations might also exhibit marginal constraint from the point of view of dynamic stability [6, 7]. Mechanical stability reflects the impossibility of reducing the volume occupied by the system through a continuous motion of its particles such that the volume does not increase at any time during the motion [8]. Dynamic stability reflects the impossibility of reducing the volume even through motions that cause small rearrangements in the contact network, and which might at first increase the volume. Wyart showed that marginal dynamic stability is associated with power-law distributions of the gaps between pairs of spheres that are nearly in contact – called quasicontacts – and of the forces between pairs of spheres that are in contact, but exert a nearly zero contact force on each other [6].

In Sections II–III, we will consider MRJ configurations of frictionless hard spheres in a Euclidean space of $d$ dimensions and study the abundance of quasicontacts. Recently, many works have been devoted to identifying the asymptotic scaling behavior of various densities associated with MRJ packings and the prejamming dynamics of hard-sphere fluids in the limit $d \to \infty$, and this question has lead to many advances in the theory of jamming and the glass transition [9,11]. We will show that the abundance of quasicontact, required for reasons of dynamic stability, imposes strong structural constraints
that are as important as those imposed by the network of mechanical contacts. The power-law singularities of active constraints on the verge of becoming inactive and vice versa are not unique to MRJ packings, and they arise in other disordered systems [14]. In Sections IV–V, we analyze jammed Bravais lattice sphere packings, which are closely related to MRJ packings.

The dimensional dependence of the number of mechanical contacts around an average sphere can be easily derived from Maxwellian constraint counting: since each contact is incident on two spheres and imposes one constraint, and each sphere has $d$ translational degrees of freedom, each sphere should have, on average, $2d$ contacts. Quasicontacts, on the other hand, do not contribute to mechanical stability, but clearly participate in the trapping behavior as a configuration dynamically approaches the jamming point. These contacts show up as a power-law divergence of the pair-correlation function near the contact distance (historically, this was known as the “square-root divergence,” but the power-law exponent is no longer agreed to be $1/2$) [9 10 17]. Quasicontacts are challenging to study, because unlike mechanical contacts, identifying specific pairs as quasicontacts requires the definition of an arbitrary cutoff distance [18] or another criterion, such as adjacency of Voronoi regions [19]. Since this divergent part of the pair correlation overlaps with the well-behaved part, we do not attempt to identify specific pairs as quasicontacts and only study the influence of the abundance of pairs at small separations.

II. QUASICONTACTS IN DISORDERED PACKINGS

We would like to understand the characteristics of the quasicontact and weak contact distributions as a function of dimension. The calculation of Ref. [6] is set in a fixed number of dimensions but applies equally well in any dimension. We must only reintroduce the dimensional dependence that was originally left out in order to determine the expected number of quasicontacts around the average sphere. Consider an MRJ packing of $N$ unit-diameter spheres with centers $r_k$, $k = 1, \ldots, N$. Isostaticity guarantees that for any contact $(i, j)$, there exists a continuous motion $\delta r_k(s)$ of the sphere centers such that the distance between the centers of the spheres $i$ and $j$ is $1 + s$, and the distance between the centers of any other pair originally in contact remains 1. In the process of this motion, the work performed by the packing is given by

$$p\delta V = f_{ij}s - \sum_{(k,l)\neq (i,j)} f_{kl}||\delta r_k - \delta r_l||_{\text{tang}}^2$$

$$= f_{ij}s - C_{ij}s^2 + o(s^2),$$

where $f_{kl} > 0$ is the magnitude of the force between $k$ and $l$ in the original packing, and $(v)_{\text{tang}}$ denotes the component of the vector $v$ in the plane tangent to the spheres $k$ and $l$ in the original packing [6]. At some value of $s = s_c$, a pair that was previously separated by a gap will come into contact, and the motion is unphysical beyond this terminal point. At a value $s^* \sim f_{ij}/C_{ij}$, the volume will start to decrease beyond its original value. The packing is considered stable if for every single-contact-breaking motion, the volume at the terminal point $s_c$, is increased compared to the original volume, i.e., if $s_c$ is of the order of $s^*$ or smaller for all contacts. If violated at all, this stability criterion will be violated by a contact whose force is of the same order as the weakest contact, and the gap closed will have a width of the same order as the smallest gap. We will assume that the average number of non-contact-neighbor centers at a distance of $r = 1 + \xi$ or less from the center of a randomly chosen sphere is $Z_{nc}(\xi) \simeq A_d\xi^{1-\gamma}$ for $0 < \xi \ll 1$, (2)

where $A_d$ is the dimension-dependent amplitude of the quasicontact singularity. Similarly, we assume that the probability density of the force at a randomly chosen contact is given by

$$P(f) \simeq f^\theta/(f)^{1+\theta} \text{ for } 0 < f \ll \langle f \rangle,$$

where $\langle f \rangle$ is the average contact force and is proportional to the externally applied pressure $p$. Then the smallest gap is of size roughly such that $\frac{1}{2}N[Z(\xi_{\text{min}}) - 2d] = 1$, and so $\xi_{\text{min}} \sim (A_dN)^{-1/(1-\gamma)}$. Similarly, as the total number of contacts is $dN$, the weakest contact is roughly of strength $f_{\text{min}} \sim (dN)^{-1/(1+\theta)}\langle f \rangle$. We assume, as in Ref. [6], that all single-contact-breaking motions extend to the entire system, and that each sphere moves by a distance proportional to $s$ along each coordinate in a roughly uncorrelated way. We therefore have that $C_{ij} \sim d^2N\langle f \rangle$, irrespective of the strength of the contact broken. Therefore, for stability, we require that $s_c \sim \xi_{\text{min}} \sim (A_dN)^{-1/(1-\gamma)}$ be of the same order or smaller order than $s^* \sim d^{-1/(1+\theta)}2N^{-1/(1+\theta)} - 1$. From the dependence on $N$, we obtain the inequality derived in Ref. [6], $\gamma \geq 1/(2 + \theta)$.

Recall that mechanical stability required more contacts than degrees of freedom, and the fact that MRJ packings lie at the margin between instability and stability implied that this criterion would be satisfied with equality. Here, too, we may predict that the inequalities we derive as criteria for dynamical stability will be satisfied with equality, as a sign of marginal stability. From the dependence on $d$, we have that the amplitude of the quasicontact singularity $A_d$ must increase as $d^\nu$ with $\nu \geq (1-\gamma)(3+2\theta)/(1+\theta)$, with equality under the assumption of marginal stability. If we assume equality in both cases, we obtain $\nu = 2 - \gamma$. Note that we assume that the exponents $\gamma$ and $\theta$ are independent of dimension. We do not know of any arguments from first principles that justify this assumption, but it is supported by simulation results [9 20], and theoretical calculations in the limit $d \rightarrow \infty$ [14].

In a later paper, Lerner, Düring, and Wyart also analyzed the case of contacts that are weak because their
contact-breaking motion does not extend to the entire system. We address that case in Appendix A, where we find that $\tilde{\nu} = 2 - \gamma$ also in the case that this type of contacts dominates. As typical values for the power-law exponents seem to be not much different from $\gamma \approx 0.4$ and $\theta \approx 0.3$ \[9, 16, 17\], we expect the number of quasicontacts to rise much faster as a function of dimension than the number of contacts does. The mechanical description of a packing depends only on the force-carrying contacts, not quasicontacts. However, from a geometric point of view, contacts and quasicontacts are nearly indistinguishable. Therefore, the number of quasicontacts, not only the number of mechanical contacts, is likely to be a key determinant of the structure of MRJ packings in high dimensions.

### III. EFFECT OF QUASICONTACTS ON DENSITY

To study the effect of quasicontacts, we will revisit a calculation of Jin et al. \[12\], in which quasicontacts are originally neglected. Specifically, we will introduce their presence into the calculation. The original calculation, presented in Ref. \[12\], was inspired by an earlier calculation \[21\] limited to three dimensions, and derives the density of a disordered packing in $d$ dimensions based on the expectation value of the Voronoi region surrounding an arbitrary sphere. The calculation is based on two assumptions: (i) a simplified form for the pair correlation function,

$$g(r) = \Theta(r - 1) + \frac{z \delta(r - 1)}{\rho S_{d-1}},$$

where $z = 2d$ is the average contact number, $\Theta$ is the Heaviside step function, $\delta$ is the Dirac delta function, $S_{d-1}$ is the $(d-1)$-dimensional surface area of the unit sphere, and $\rho = N/V$ is the number density of the packing; and (ii) after choosing the origin to be the center of the sphere whose Voronoi region is to be calculated, the centers of all other spheres are assumed to be uncorrelated with each other, distributed according to a random process whose radius-dependent density is given by $\rho g(r)$ \[22\]. The two assumptions are motivated by the principle of decorrelation in high dimensions, which posits that as the spatial dimension increases, unconstrained spatial correlations tend to vanish \[23\]. Indeed, the features of the pair correlation function away from $r = 1$ appear to flatten out as the dimension increases (see, e.g., Figure 7 of Ref. \[24\]). However, the quasicontact divergence, which is neglected in the form of $g(r)$ given in \[4\] remains prominent.

The calculation proceeds by noting that a point at a distance $c$ from the origin is within the Voronoi region if and only if the spherical region of radius $c$ surrounding that point does not contain any sphere centers in its interior (see Figure 1, where this region is denoted as $\Omega(c)$). The assumption (ii) gives rise to the rule that the probability that a region of space $\Omega$ contains no sphere centers is given by

$$P(N_\Omega = 0) = \exp(-\langle N_\Omega \rangle),$$

where $N_\Omega$ is the number of sphere centers in $\Omega$. This ansatz ignores all correlations between different spheres. In reality, the hard-core repulsion interaction implies a negative correlation between different spheres \[25\], and so \[5\] should be taken as an upper bound in the two-sided inequality

$$1 - \langle N_\Omega \rangle < P(N_\Omega = 0) < \exp(-\langle N_\Omega \rangle),$$
where the left-hand side represents perfect anticorrelation and the right-hand side represents no correlations. Note that the right-hand side is a particularly poor approximation of \( P(N_{\Omega(c)} = 0) \) when \( \frac{1}{3} < c \leq \sqrt{1/3} \). In that case, the left-hand side is actually exact, since \( \Omega(c) \) can contain at most one sphere center.

In the limit of very high dimensions, Jin et al. are able to show that, given their assumptions, the density of the packing is given asymptotically by \( \varphi \sim d^d \nu^d \) with \( \nu = 1 \). Indeed, it has been shown that this density is a rigorous upper bound for any packing that possesses a single sphere center.

We show in Appendix B that under this modified assumption, \( \nu = \max(1, \bar{\nu} + \gamma - 1) \), where the first argument of the maximum represents the effect of contacts, the second represents the effect of quasicontacts, and the larger of the two dominates. Since we have seen that marginal stability implies that \( \bar{\nu} = 2 - \gamma \), we have the unexpected result that in marginally stable packings, neither contacts nor quasicontacts dominate the effect of the other on the scaling of the density derived in this calculation.

The presence of quasicontacts does affect the prefactor of the asymptotic form of the density. The calculation of Jin et al. predicts \( 2^d \varphi \approx 1.33d \). Using a value of \( \gamma = 0.42 \), the calculation of Appendix B gives \( 2^d \varphi \approx (1.33 + 1.00c)d \), where \( A_d \approx \bar{c}d^{d-\gamma} \). To approximate the magnitude of the added term, we estimate \( c \approx 3.7 \) by fitting \( A_d = \bar{c}d^{1.5} \) to values of \( A_d \) measured in numerical simulations in dimensions 3–10 [9]. Therefore, it appears that the quasicontact contribution is considerably more significant than the contact contribution in this calculation. It also helps close the large gap that has been present between the prediction of Jin et al. and other theoretical predictions that give the same scaling exponent but a much larger prefactor, such as the prediction \( 2^d \varphi_{\text{K}} \approx 6.26d \) of Ref. [11]. Note that in cases in which the dynamic stability criteria of Section I are satisfied with inequality rather than equality, quasicontacts are predicted to dominate. Note also that if the assumption (ii) is reinterpreted as an upper bound as in [6], then the calculated density can be seen as a lower bound, \( \nu \geq \max(1, \bar{\nu} + \gamma - 1) \).

IV. QUASICONTACTS IN LATTICE PACKINGS

While the presence of quasicontacts turns out not necessarily to affect the asymptotic scaling exponent of the density in MRJ packings, we show next that it does likely have an effect in marginally stable jammed Bravais lattice packings. Bravais lattice packings are periodic packings of spheres with one sphere per unit cell. Recently, we explored an ensemble of jammed (mechanically stable) Bravais lattices generated by a sequence of compressions in dimensions \( d = 15–24 \) [20, 26, 27]. Almost all of these lattices were found to possess the bare minimum number of contacts required for mechanical stability of a Bravais lattice, namely \( z = d(d + 1) \), and the pair correlation and force distribution of these jammed lattices exhibited power-law tails. These findings suggest that these lattices are marginally stable with respect to both static and dynamics stability, and should therefore be regarded as an analog of MRJ packings in the context of Bravais lattices. Bravais lattices with the minimal contact number \( z = d(d + 1) \) are hyperstatic, since \( z > 2d \), and indeed they can remain mechanically stable even after an extensive number of contact constraints are relaxed. However, if any contact constraint is relaxed together with all of its periodic images, then the system loses its mechanical stability. Therefore, with the idea of considering a single unit cell as our system and the removal of one constraint entailing the removal of its images in all other unit cells, we will refer to these lattices as isostatic in this specific context, despite the fact that the packing as a whole is hyperstatic [20].

The power-law tails of the pair correlation and force distribution function were found to have dimensionally-independent exponents \( \gamma = 0.314 \pm 0.004 \) and \( \theta = 0.371 \pm 0.010 \) respectively, and the prefactor of the quasicontact singularity was found to grow as a power law \( A_d \sim d^\nu \), with \( \nu = 3.30 \pm 0.05 \) [20]. Before considering the effect of quasicontacts on the typical density of these lattices, we begin by translating the calculation of Ref. [6] to the context of Bravais lattices in order to derive a stability criterion in terms of the exponents \( \gamma, \theta, \) and \( \bar{\nu} \).

The problem of lattice sphere packing can be formulated as the problem of determining a symmetric, positive definite matrix \( G \) of minimal determinant, such that \( \langle n, G n \rangle \geq 1 \) for all nonzero integer vectors \( n \in \mathbb{Z}^d \) [28]. The centers of the spheres then take the positions \( M \vec{n} \), where \( M \) is some matrix such that \( G = M^T M \), and the density is \( \varphi = \frac{1}{2^d \sqrt{\det G}} \). The jammed packings occur as locally optimal solutions of this optimization problem, and such lattices are known as extreme lattices [29]. The minimum number of contacts in an extreme lattice is \( d(d + 1) \), corresponding to equality between the number of degrees of freedom in \( G, \frac{1}{2}d(d + 1) \), and the number of active constraints (the constraints \( \langle n, G n \rangle \geq 1 \) and \( -\langle n, G(n) \rangle \geq 1 \) are equivalent) [29]. Extreme lattices with this minimum contact number are called isostatic lattices [20] or minimally extreme lattices [30]. We label a set of integer vectors responsible for all inequivalent contacts as \( n_k, k = 1, \ldots, d(d + 1)/2 \). From the method of Lagrange multipliers we have that at a local minimum

\[
\det G G^{-1} = \sum f_k n_k n_k^T,
\]
where the contact forces \( f_k \) are positive. The average force is \( \langle f \rangle = 2(\det G)/(d+1) \)
[20].

For any contact \( n_i \) in a minimally extreme lattice, there is a motion \( \delta G_i(s) = sG'_i \), such that \( (n_i, \delta G_i(s)n_i) = s\delta \) for all \( k = 1, \ldots, d(d+1)/2 \). This motion can continue until at some \( s_c \) there is an integer vector \( n_c \) that does not correspond to an original contact and becomes a contact \( (n_c, (G + sG'_i)n_c) = 1 \). The identity \( \det(1 + X) = \exp(\sum_{n=1}^{\infty} (-1)^n/n) \) allows us to expand the determinant of \( G + sG'_i \) as a power series:

\[
\frac{\det(G + sG'_i)}{\det G} = 1 + s \det G^{-1}G'_i + \frac{s^2}{2} [\langle tr G^{-1}G'_i \rangle^2 - \langle tr G^{-1}G'_i G^{-1}G'_i \rangle] + o(s^2).
\]

We use [8] to obtain

\[
(\det G)(\langle tr G^{-1}G'_i \rangle) = \sum_k f_k \langle n_k, G'_i n_k \rangle = f_i,
\]

\[
(\det G)^2(\langle tr G^{-1}G'_i G^{-1}G'_i \rangle) = \sum_{j,k} f_j f_k \langle n_j, G'_i n_k \rangle^2.
\]

Therefore, the change in the determinant of \( G \) along the single-contact-breaking motion is given by \( \delta(\det G) = f_is - C_is^2 + o(s^2) \), where

\[
C_i = \frac{1}{2\det G} \sum_{j \neq k} f_j f_k \langle n_j, G'_i n_k \rangle^2.
\]

The typical magnitude of \( C_i \) is given by \( C_i \sim d^4(\det G)^{-1}\langle f \rangle^2 \). For stability, we need \( s_c \), the maximum physical extent of the motion associated with breaking a contact carrying a force of the order of the weakest force, to be smaller than the extent \( s^* \) for which \( \delta(\det G) = 0 \).

Since we have \( \sim d^2 \) contacts, the smallest force is typically \( f_{\text{min}} \sim d^{-2/(1+\theta)} \langle f \rangle \), where \( (\langle f \rangle) \sim (\det G)/d \). If the average number of non-contact lattice points at a distance less than \( r = 1 + \xi \) is \( Z_{\text{nc}}(\xi) = A_d\xi^{1-\gamma} \) for \( 0 < \xi \ll 1 \), then the width of the smallest gap is of order \( \xi_{\text{min}} \sim A_d^{1/(1-\gamma)} \sim d^{-\nu/(1-\gamma)} \).

Therefore, for stability we require that \( s^* \sim (d^{-2/(1+\theta)}(\langle f \rangle))/(d^4(\langle f \rangle)^2(\det G)^{-1}) \sim d^{[\gamma + \theta]/(1+\theta)} \) be of the same order or larger than \( d^{-\nu/(1-\gamma)} \). We have stability if \( \nu \geq (1-\gamma)(5+3\theta)/(1+\theta) \), and marginal stability in the case of equality. This inequality appears to be satisfied and nearly saturated based on the values of the exponents derived from numerical simulations in dimensions \( d = 15 - 24 \): \( \nu \approx 3.30 \pm 0.05 \), \( \gamma = 0.314 \pm 0.004 \), \( \theta = 0.371 \pm 0.010 \) and \( (1-\gamma)(5+3\theta)/(1+\theta) = 3.06 \pm 0.02 \).

Since the principle of decorrelation applies also to lattice configurations [20,31], the assumptions of the calculation of Jin et al. should apply for lattices in high dimensions to the same extent that they do for MRJ packings. For lattices with the minimum number of contacts required for mechanical stability, the contact number is \( z = d(d+1) \). Therefore the calculation yields the density estimate (or lower bound, if the second assumption is interpreted as a bound) \( \varphi \sim d^22^{-d} \), where

\[ \nu = \max(2, \nu + \gamma - 1) \approx 2.61 \). In this case the second term of the maximum dominates and the quasi-contact abundance is predicted to have a significant effect on the asymptotic scaling of the density. However, as we observe in Appendix B, the effect of quasicontacts is only expected to dominate the effect of contacts in relatively high dimensions. The calculation suggests that the former overtakes the latter around \( d \approx 5000 \), much higher than the dimensions explored thus far in simulations.

With this observation in mind, we should be careful in
using low-dimensional data to extract high-dimensional scaling. However, it seems clear from the data that the densities of both MRJ packings and jammed Bravais lattice packings increase at a much higher rate than predicted by our calculation (see Figure 2). It is reasonable to conclude that the assumption (ii) neglects important anti-correlations in these packings. Nevertheless, the interpretation of our calculation as a lower bound is sound, since it is not expected that a less simplified approximation of $g(r)$ than that of assumption (i') would yield a dramatic decrease in the predicted density.

V. BREAKDOWN OF THE EDWARDS ENSEMBLE ANSATZ

Jammed lattice packings also provide a useful system for studying Edwards statistical mechanics. Edwards proposed to investigate granular materials by considering ensembles that bear a formal resemblance to classical thermodynamic ensembles but replace energy conservation with volume conservation \cite{1979}. The Edwards canonical ensemble gives a weight proportional to $\exp(-XV)$ to any mechanically stable configuration occupying a volume $V$ and zero weight to non-stable configurations. The compactivity $X$ takes the role of inverse-temperature in the classical canonical ensemble. For the case of lattices, the mechanically stable configurations correspond to extreme lattices. Voronoi proposed an algorithm to completely enumerate perfect lattices, a superset of extreme lattices, in a given dimension, and this full enumeration has been performed in dimensions up to $d = 8$ \cite{2002}. In eight dimensions, there are 10,916 perfect lattices, out of which 858 are minimally extreme \cite{2008}. We can therefore study the Edwards ensemble exactly for $d = 8$. We focus on the distribution of contact forces, since the distribution of gaps is still far from continuous for $d = 8$. In Figure 3, we show the distribution of contact forces in the Edwards ensemble for zero compactivity. Note that there appears to be a finite probability density at $f = 0$, in contrast with the expected power-law behavior. We suspect that this is not only the case for zero compactivity, but unfortunately the available sample in $d = 8$ is not large enough to discern a clear-cut violation of the power-law behavior for compactivities large enough so that only a small part of the sample has statistical weight. However, we note that the violation appears to persist even when looking at only the 200 densest minimally extreme lattices, but the statistical significance is much lower due to larger fluctuations.

VI. CONCLUSION

In this paper we have investigated from a few different directions the power-law singularities of the pair correlation function near the contact distance and of contact force probability density near zero force. These singularities arise in MRJ packings and in their recently identified relatives, jammed Bravais lattice packings. In both cases, they appear to be signatures of the fact that these configurations lie at the margin between overconstraint and underconstraint in terms of dynamic stability, much like isostaticity is related to marginal mechanical stability. As we have seen in the case of Bravais lattice packings, power-law tails in the distributions of active constraints on the verge of becoming inactive and vice versa might also arise in other scenarios in which cost is minimized in a quenched frustrated system subject to many competing inequality constraints.

We showed that quasicontacts, the pairs of spheres contributing to the power-law singularity in the pair correlation function, become much more abundant at high dimensions than actual contacts. Since from a geometric, rather than a mechanical, perspective, quasicontacts can be nearly indistinguishable from contacts, they could have a significant effect on the geometric structure of MRJ packings in high dimension. Indeed, we show that a calculation of the density based on a simplified model of correlations predicts that contacts and quasicontacts both contribute to the leading term of the asymptotic dependence of the density on dimension, which is calculated to be $\varphi \sim d^{\nu/2-d}$, with $\nu = 1$. In fact, it seems that the contribution due to quasicontacts is significantly larger than that due to contacts. Moreover, in the case of Bravais lattices, the calculation predicts that the quasicontact contribution dominates asymptotically.

Finally, we showed that in the case of Bravais lattices of dimensions not too high, it is possible to directly study the Edwards ensemble. We considered the distribution of contact forces in the Edwards ensemble of Bravais lattices in $d = 8$, but we were unable to reproduce a power-law behavior for near-zero forces. As we have argued, the power-law behavior of weak contacts and quasicontacts is a consequence of dynamic effects, an end product of an unstable system driven out of equilibrium to the edge of stability, and we should not be surprised that a theory based on equilibrium methods positing only static stability does not reproduce it.

Appendix A

In the main text we considered the stability of a disordered packing with respect to motions that break a
weak contact and extend to the entire packing. In Ref. [7], the authors demonstrated the existence of contacts that lead to localized contact-breaking motions and claim that such contacts dominate the distribution of weakest contacts. As we showed in the main text, the contact force \( f_{ij} \) is identified with the first-order derivative \( \lim_{s \to 0} p \tilde{V}'(s)/s \) of the rate of work done upon opening the contact into a gap of width \( s \), maintaining all other contacts. Lerner et al. decomposed the contact force \( \tilde{f}_{ij} = b_{ij} w_{ij} \) into two factors: \( b_{ij} \) measures how strongly the contact-breaking motion couples to the bulk, i.e., the \( f \) contacts. Lerner et al. decomposed the contact force into a gap of width \( s \) where \( \lim_{s \to 0} f_{ij} \) is identified with the first-order derivative \( \tilde{f}_{ij} \) that lead to localized contact-breaking motions and claim that such contacts dominate the distribution of weakest contacts.

The case treated in the main text corresponds to the case in which the weak contact distribution is dominated by contacts with \( b_{ij} \sim 1 \) and \( w_{ij} \) is distributed according to \( P(w) \sim w^\rho \). In this appendix we treat the case in which \( w_{ij} \sim 1 \) and \( b_{ij} \) is distributed according to \( P(b) \sim b^\theta \).

While spheres in the bulk move by distances \( \sim bs \), where \( b \ll N^{-1/2} \), the number of spheres that move by distances \( \sim s \) does not increase with the system size. However, because the average number of contacts around a sphere is \( 2d \), the number of spheres involved in the localized motion will increase with dimension as \( \sim d \). Since the gap whose closing defines the physical extent \( s_c \) of the motion is likely to be far away from the contact being opened, we have \( s_c \sim \xi_{\min}/b_{ij} \sim \xi_{\min}/(f_{ij}/f) \), where \( \xi_{\min} \sim (A_d N)^{-1/(1-\gamma)} \) is the smallest gap in the packing. Meanwhile, \( C_{ij} = \lim_{s \to 0} \sum_{(k,l) \neq (i,j)} f_{kl} ||(\delta r_k - \delta r_l)|^2/s^2 \), the coefficient that controls the second-order change in volume, is dominated by the \( \sim d \) spheres involved in the localized motion, which move a distance \( \sim s \). Therefore, the typical value of \( C_{ij} \) for these contacts is \( \sim d(f) \) and \( s^* \sim f_{ij}/C_{ij} \sim d^{-1}(f_{ij}/f) \). For contact forces of the same order as the weakest contact, \( f_{\min} \sim (dN)^{-1/(1+\theta)} \), stability requires that \( s_c \sim d^{-\theta/(1-\gamma) + 1/(1+\theta)} N^{-1/(1-\gamma) + 1/(1+\theta)} \) be of the same order or smaller order than \( s^* \sim d^{-1-1/(1+\theta)} N^{1/(1+\theta)} \). The conclusion is that the criteria for stability are \( \gamma \geq (1 - \theta)/2 \) and \( \tilde{\nu} \geq (1 - \gamma)(3 + \theta)/(1 + \theta) \). If we assume equality in both cases, we obtain \( \tilde{\nu} = 2 - \gamma \). Therefore, no matter which kind of contacts dominate the distribution of weakest contacts, we obtain the same prediction for the exponent controlling the dimensional growth of the abundance of quasiconnections.

### Appendix B

In this appendix, we derive an asymptotic expression for the density of an MRJ packing in the limit of high dimensions by calculating the expected volume of the Voronoi region associated with a typical sphere in the packing. The calculation is based on two assumptions:

(i) a simplified form [7] for the pair correlation that includes terms corresponding to contacts, quasiconnections, and bulk spheres, and (ii) a lack of significant correlations between spheres other than the pair correlations involving the central sphere whose Voronoi volume is being calculated. This latter assumption is expressed by the ansatz [6] which can alternatively be interpreted as a bound [6].

The expected volume of the Voronoi region is given by

\[
\rho^{-1} = \langle v \rangle = 2^{-d} S_{d-1} / d + \int_{c=1/2}^{\infty} S_{d-1} \, \epsilon^{d-1} P(c) \, dc,
\]

where \( P(c) \) is the probability that a point at a distance \( c \) from the origin is inside the Voronoi region. Note that (B1) simply reflects the additivity of the expectation value of the volume of intersection of the Voronoi region with any region of space, regardless of correlations. Therefore, it is exact in every dimension, provided a correct form of the function \( P(c) \).

We use assumption (ii) to give an approximation of \( P(c) \), the probability that the region \( \Omega(c) \) contains no sphere centers (see Figure 1):

\[
P(c) = \exp(-\langle N_D(c) \rangle) = \exp\left(-\int_{r=1}^{2c} r^{d-1} \rho g(r) S_{d-1} f_0(r) dr \right),
\]

where \( \Omega(c) \) is a spherical region of radius \( c \) whose center is a distance \( c \) from the origin, and \( 0 \leq f_0(r) \leq 1 \) is the fraction of a spherical surface of radius \( r \) centered at the origin that intersects \( \Omega(c) \). The fraction \( f(x) \) of the sphere at a latitude of less than \( \arccos x \) from the pole is given by the integral

\[
f(x) = \frac{S_{d-2}}{S_{d-1}} \int_{t=x}^{1} (1 - t^2)^{d-3/2} \, dt.
\]

We may decompose \( P(c) = P_B(c) P_C(c) P_Q(c) \) into independent terms corresponding to spheres in the bulk, contacts, and quasiconnections respectively. We have

\[
\log P_B(c) = -\rho S_{d-1} \int_{r=1}^{2c} r^{d-1} f_0(\frac{r}{2c}) dr
\]

\[
= -\frac{\rho}{d} S_{d-2} \int_{t=1/2c}^{1} (1 - t^2)^{d-3/2} (2t^d dt - 1) dt
\]

\[
= -\frac{\rho}{d} S_{d-1} \epsilon^{d}(1 - f(1 - \frac{1}{2c})) + \frac{cs_{d-2}}{(d-1)S_{d-1}} \left(1 - \frac{1}{d-1}\right)^{d-1} - f(\frac{1}{2c}));
\]

\[
\log P_C(c) = -zf(\frac{1}{2c});
\]

and

\[
\log P_Q(c) = -(1 - \gamma) A_d \int_{r=1}^{2c} (r - 1)^{-\gamma} f_0(\frac{r}{2c}) dr
\]

\[
= -A_d h_{\gamma}(\frac{1}{2c}),
\]
where

\[ h_\gamma(x) = \frac{S_{d-2}}{S_{d-1}} \int_{t=x}^1 (1 - t^2)^{\frac{d-3}{2}} (\frac{t}{x} - 1)^{1-\gamma} dt. \]  

(B7)

Note that \( f(x) = h_1(x) \).

We let \( w = (2^d x)^{-1} = d/(\rho S_{d-1}) \) and obtain the equation which determines \( w \) implicitly,

\[ 1 = \frac{2-d}{w} + \int_{c=1/2}^{\infty} e^{c-1} w^{-1} e^{w^{-1}} H(c;w) \, dc \]

\[ = \frac{2-d}{w} + \int_{y=2-\frac{d}{w}}^{\infty} e^{-y+H(y^{1/d}; w)} \, dy, \]

where

\[ H(c; w) = \frac{e^d}{w} f(1 - \frac{1}{2\pi}) - \frac{cS_{d-2}}{(d-1)wS_{d-1}}(1 - \frac{1}{4\pi})^{d-1} \]

\[ + (\frac{1}{w} - z)f(\frac{1}{2\pi}) - Awh_\gamma(\frac{1}{2\pi}). \]  

(B9)

For large \( d \), we expect that \( 2-d/w \to 0 \) and we may write \( \int_{y=0}^{\infty} e^{-y+H(y^{1/d}; w)} \, dy \approx 1 \). Using the fact that \( H(c; w) \) behaves nicely, we conclude that \( w \) is such that \( H(y^{1/d}; w) \approx 0 \) when \( y \approx 1 \).

We now turn to the task of approximating the functions \( h_\gamma(x) \) and \( f(x) = h_1(x) \) when \( d \gg 1 \) and \( x \ll 1 \). We write \( (1 - t^2)^{d-3} \) as \( 2^{-\frac{d}{2}} \exp(\log(1-t^2)) \) and use Laplace's method by expanding the argument of the exponential function about the point where it takes its largest value in the integration domain, which in this case is the lower bound \( t = x \):

\[ \log(1-t^2) \approx \log(1-x^2) + \frac{x^2}{1 + x^2} - \frac{1 + x^2}{(1-x^2)^2} \left( t - x + \frac{x(1-x^2)}{1 + x^2} \right)^2. \]  

(B10)

If we let \( s = (d-3)^{\frac{1}{2}} (1 + x^2)^{\frac{1}{2}} (t-x)/(1-x^2) \), we obtain an integral of the form

\[ h_\gamma(x) \approx \frac{S_{d-2}(1-x^2)^{\frac{d-3}{2} + 2-\gamma}}{S_{d-1}(d-3)^{\frac{2-\gamma}{2}} (1 + x^2)^{\frac{3-\gamma}{2}} x^{1-\gamma}} \times e^{\frac{1}{2} \int_{s=0}^{\infty}} e^{-\frac{(s+s_0)^2}{2}} s^{1-\gamma} ds, \]

where \( s_0 = (d-3)^{\frac{1}{2}} x/(1 + x^2)^{\frac{1}{2}} \). The last integral can be asymptotically expanded in powers of \( 1/s_0 \) by performing a change of variables, expanding the resulting binomials, and integrating term by term. We only require the first term of the expansion:

\[ e^{\frac{1}{2} \int_{s=0}^{\infty}} e^{-\frac{(s+s_0)^2}{2}} s^{1-\gamma} ds \]

\[ = \frac{1}{2} s_0^{2-\gamma} \int_{u=0}^{\infty} e^{-\frac{s_0^2 u}{2}} \left( (1+u)^{\frac{1}{2}} - 1 \right)^{1-\gamma} (1+u)^{-\frac{1}{2}} du \]

\[ \approx \frac{1}{2} s_0^{2-\gamma} \int_{w=0}^{\infty} e^{-\frac{s_0^2 u}{2}} (w^{1-\gamma}) du = s_0^{2-\gamma}(2-\gamma). \]  

(B12)

We therefore obtain the asymptotic forms for \( h_\gamma(x) \) and \( f(x) = h_1(x) \):

\[ h_\gamma(x) \approx \frac{S_{d-2} \Gamma(2-\gamma)(1-x^2)^{\frac{d+1-\gamma}{2}}}{S_{d-1}(d-3)^{\frac{1-\gamma}{2}}} \]

\[ f(x) \approx \frac{S_{d-2}(1-x^2)^{\frac{d-1}{2}}}{S_{d-1}(d-3)^{\frac{1-\gamma}{2}}}. \]  

(B13)

(B14)

The latter of these agrees with the asymptotic form derived in Ref. [12]. Finally, then, we have that \( H(w^{1/d}; w) \approx 0 \) when

\[ \frac{1}{2} - \frac{d-3}{2d-2} + 1 - wz \]

\[ wA_d \Gamma(2-\gamma) \frac{(1 - \frac{1}{2}w^2-rac{3}{2})(2w^2)^2}{(d-3)^{1-\gamma}} \approx 0. \]  

(B15)

So if \( A_d \approx d^\nu \) and \( z \approx d^\nu \), then \( w \sim d^{-\nu} \), where \( \nu = \max(\nu_\gamma, \nu + \gamma - 1) \). If the first argument of the maximum dominates we have \( \varphi = 2^{-d} / w \approx 2^{-d}(2z/3) \), and if the second dominates we have \( \varphi \approx 2^{-d}(2^{1-2\gamma} \Gamma(2-\gamma)A_d d^{\gamma-1}) \).

For jammed minimally extreme Bravais lattices, where \( z = d(d+1) \), numerical data for \( d = 15 - 24 \) suggests that \( A_d \approx (1.43 \times 10^{-3})d^{3.30} \) and \( \gamma \approx 0.314 \). These values imply that in the limit of high dimensions, the density estimate given by this calculation is dominated by the effect of quasicontacts. However, note that \( 2^{1-2\gamma} \Gamma(2-\gamma)A_d d^{\gamma-1} \gg \frac{2}{3} z \) only when \( d \gg 5000 \). For lower dimensions, the effect of contacts dominates or the two effects are comparable.
\[ \text{J Compu Phys 197, 139 (2004).} \]

[22] Despite the title of Ref. [12], the calculation does not use the Edwards ensemble as an assumption.
